Overview of C/S Communications

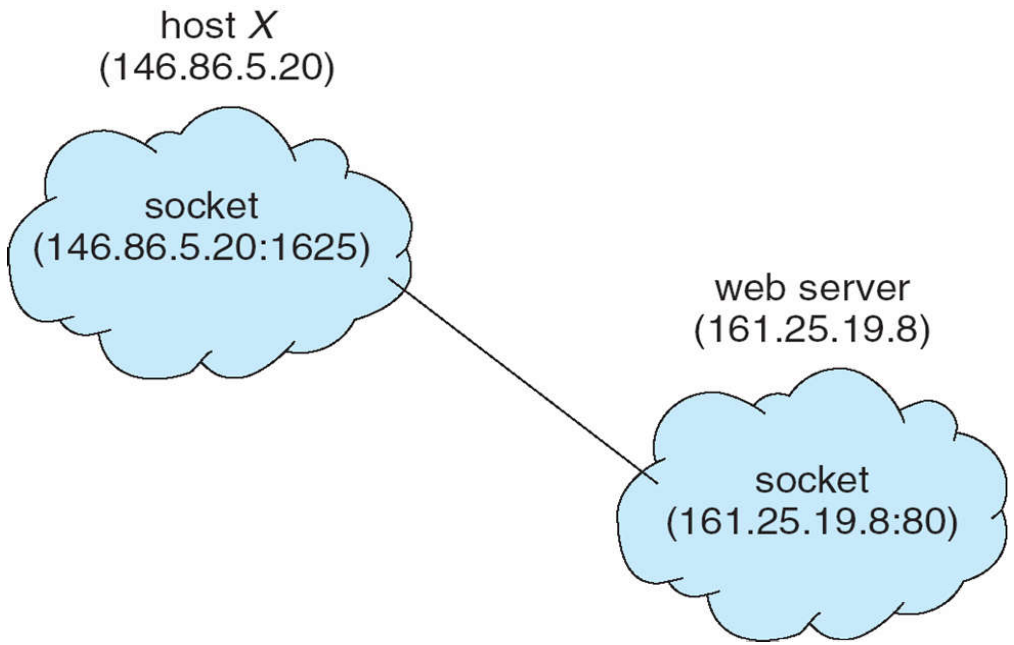
- Shared-memory and Message-passing can be used for communication in Client–Server systems as well.
- Now we explore two other strategies for communication in C/S systems
  - Sockets (Internet)
  - Remote Procedure Calls (RPCs)
    - Not only useful for C/S computing, but also used by Android as a form of IPC between processes running on the same system.

Sockets

- A socket is defined as an *endpoint* for communication.
- A pair of processes communicating over a network employs a pair of sockets—one for each process.
- A socket is a concatenation of IP address and port number.
- In general, sockets use a client–server architecture. The server waits for incoming client requests by listening to a specified port. Once a request is received, the server accepts a connection from the client socket to complete the connection.
- Servers implementing standard services listen to *well-known* ports below 1024.
  - SSH server – port 22
  - FTP server – port 21
  - HTTP server – port 80
- When a client process initiates a request for a connection, it is assigned a port by its host computer. This port has some arbitrary number greater than 1024.

Sockets

- Example.
  - Suppose that a client process on host X with IP address 146.86.5.20 wishes to establish a connection with a web server (which is listening on port 80) at address 161.25.19.8. The client may be randomly assigned a port number 1625 greater than 1024. The connection will consist of a pair of sockets (146.86.5.20:1625) on host X and (161.25.19.8:80) on the web server.



Sockets

- Example.
  - If another process also on host X wished to establish another connection with the same web server, it would be assigned a port number greater than 1024 and not equal to 1625. This ensures that all connections consist of a unique pair of sockets.

Linux: Socket Programming

Data Structures

```
#include <netinet/in.h>
struct sockaddr {
    unsigned short sa_family; /* socket address family, AF_xxx */
    char sa_data[14]; /* 14 bytes of protocol address */
};

struct in_addr {
    unsigned long s_addr;
};

struct sockaddr_in {
    short int sin_family; /* AF_INET for ipv4 */
    unsigned short int sin_port; /* Port number */
    struct in_addr sin_addr; /* IP address */
    unsigned char sin_zero[8]; /* padding with 0 to keep the same size as
struct sockaddr (16bytes) */
```

Linux: Socket Programming

Data Structures

```
#include <ifaddrs.h>
struct ifaddrs {
    struct ifaddrs *ifa_next; /* Next item in list */
    char *ifa_name; /* Name of interface */
    unsigned int ifa_flags; /* Flags from SIOCGIFFLAGS */
    struct sockaddr *ifa_addr; /* Address of interface */
    struct sockaddr *ifa_netmask; /* Netmask of interface */
    union {
        struct sockaddr *ifu_broadaddr;
            /* Broadcast address of interface */
        struct sockaddr *ifu_dstaddr;
            /* Point-to-point destination   address */
    } ifa_ifu;
#define ifa_broadaddr ifa_ifu.ifu_broadaddr
#define ifa_dstaddr ifa_ifu.ifu_dstaddr
    void *ifa_data; /* Address-specific data */
};
```

Linux: Socket Programming

- Socket APIs
  - socket() creates an endpoint for communication and returns a file descriptor (sockfd) that refers to that endpoint.

```
#include<sys/socket.h>
int socket(int domain, int type, int protocol);
```

  - bind() binds the `sockfd` to a socket address structure specified by `addr`.

```
#include<sys/socket.h>
int bind(int sockfd, const struct sockaddr *addr, socklen_t addrlen);
```

  - getsockname() returns the current address to which the socket sockfd is bound, in the buffer pointed to by addr. The `addrlen` argument should be initialized to indicate the amount of space (in bytes) pointed to by `addr`. On return it contains the actual size of the socket address.

```
#include<sys/socket.h>
int getsockname(int sockfd, struct sockaddr *restrict addr, socklen_t
*restrict addrlen);
```

Linux: Socket Programming

- Socket APIs
  - listen() sets a socket to the state of waiting for incoming connection

```
#include<sys/socket.h>
int listen(int sockfd, int backlog);
/* backlog is the number of entries in ESTABLISHED but not ACCEPTED
status. All SYN_RECV clients have to be waiting until backlog queue
has some empty space */
```

  - connect() connects the socket referred to by the file descriptor sockfd to the address specified by addr.

```
#include<sys/socket.h>
int connect(int sockfd, const struct sockaddr *serv_addr, socklen_t
addrlen);
```

Linux: Socket Programming

- Socket APIs
  - accept() is used with connection-based socket types (SOCK_STREAM, SOCK_SEQPACKET). It extracts the first connection request on the queue of pending connections for the listening socket, sockfd, creates a new connected socket, and returns a new file descriptor referring to that socket.

```
#include<sys/socket.h>
int accept(int sockfd, struct sockaddr restrict *addr, socklen_t
restrict  *addrlen);
```

  - send(): sends data to a socket.

```
#include<sys/socket.h>
ssize_t send(int sockfd, const void *buf, socklen_t len, int falgs);
```

  - recv(): receives data from a socket.

```
#include<sys/socket.h>
ssize_t recv(int sockfd, void *buf, socklen_t len, int flags);
```

Linux: Socket Programming

- Socket APIs
  - setsockopt(): setting socket options

```
#include <sys/socket.h>
int setsockopt( int sockfd, int level, int optname, const void
*optval, socklen_t optlen);
/* setsockopt() has many options */
```

  - getifaddrs(): creating a linked list of structures describing the network interfaces of the local system, and stores the address of the first item of the list in *ifap.

```
#include <sys/types.h>
#include <ifaddrs.h>
int getifaddrs(struct ifaddrs **ifap);
```

  - freeifaddrs(): freeing the data structure returned by getifaddrs() which is dynamically allocated when no longer needed.

```
#include <sys/types.h>
#include <ifaddrs.h>
void freeifaddrs(struct ifaddrs *ifap);
```

    }
```

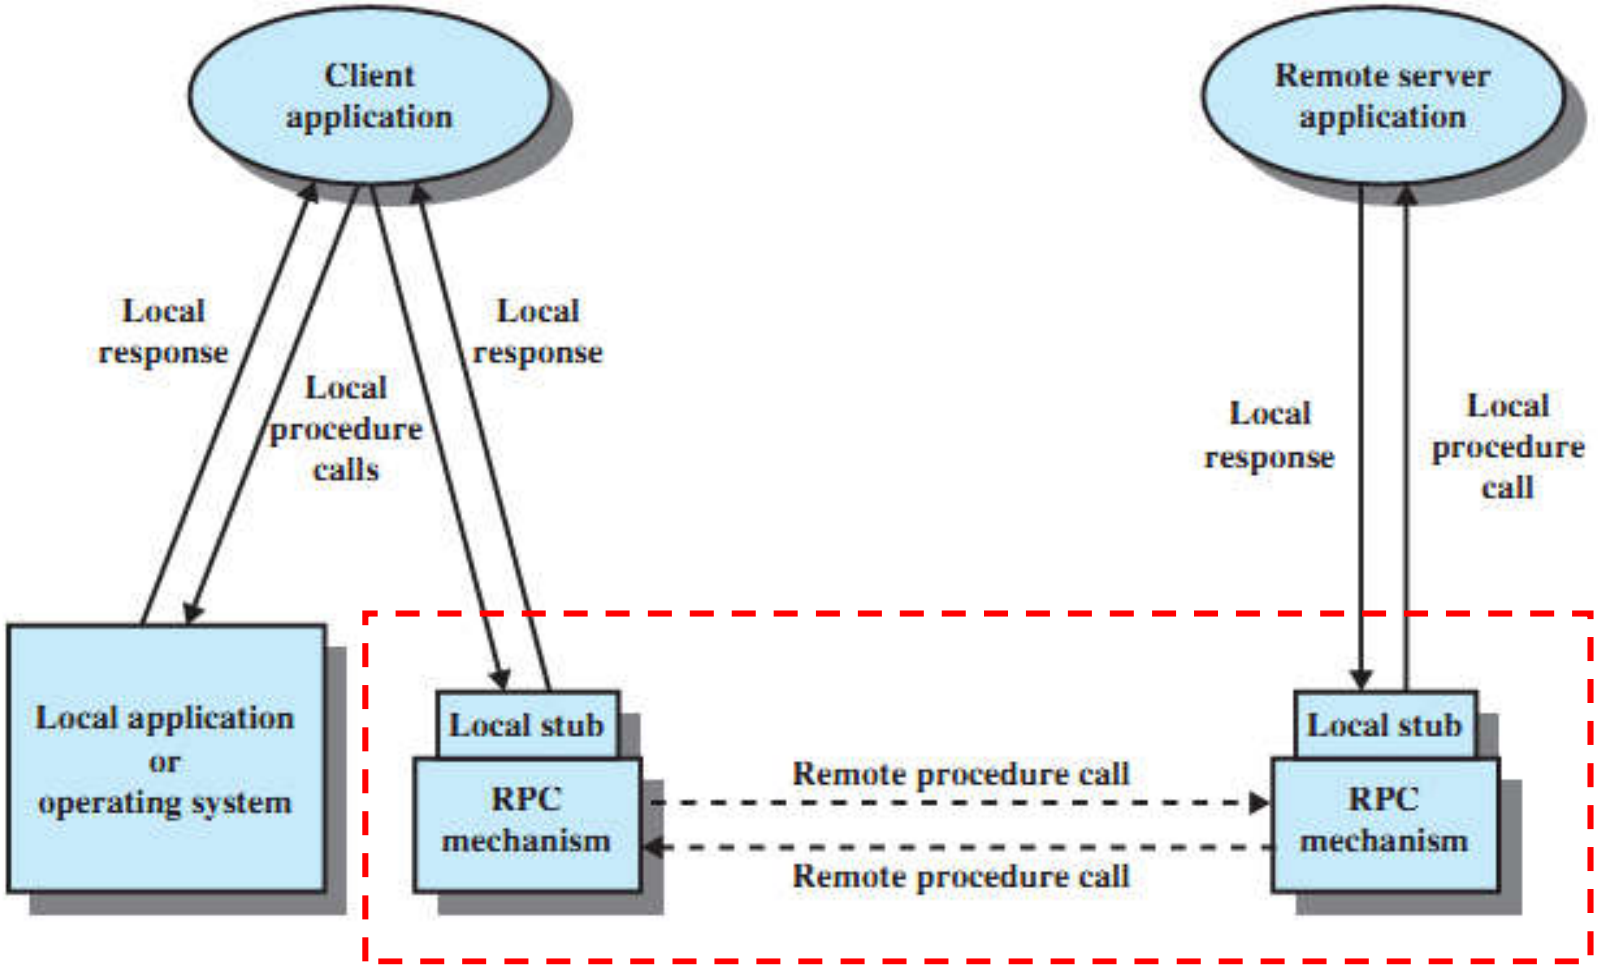
Remote Procedure Calls

- Remote Procedure Calls (RPCs) abstracts a Local Procedure Call (LPC) between processes on a networked system.
- The semantics of RPCs allows a client to invoke a procedure on a remote host as it would invoke a procedure locally. The RPC system hides the details that allow communication to take place by providing a *stub* on the client side.
  - Stubs
    - client-side proxy for the actual procedure existing on the server.
- The client-side stub locates the server and *marshals* the parameters (将参数打包).
- The server-side stub/skeleton receives this message, unpacks the marshaled parameters, and performs the procedure on the server.

Remote Procedure Calls

- RPC mechanism.



Remote Procedure Calls

- Execution of a RPC.
